Abstract Mitochondrial dysfunction is putatively central to glioblastoma (GBM) pathophysiology but there has been no systematic analysis in GBM of the proteins which are integral to mitochondrial function. Alterations in proteins in mitochondrial enriched fractions from patients with GBM were defined with label-free liquid chromatography mass spectrometry. 256 mitochondrially-associated proteins were identified in mitochondrial enriched fractions and 117 of these mitochondrial proteins were markedly (fold-change ≥ 2) and significantly altered in GBM ($p \leq 0.05$). Proteins associated with oxidative damage (including catalase, superoxide dismutase 2, peroxiredoxin

1 and peroxiredoxin 4) were increased in GBM. Protein–protein interaction analysis highlighted a reduction in multiple proteins coupled to energy metabolism (in particular respiratory chain proteins, including 23 complex-I proteins). Qualitative ultrastructural analysis in GBM with electron microscopy showed a notably higher prevalence of mitochondria with cristolysis in GBM. This study highlights the complex mitochondrial proteomic adjustments which occur in GBM pathophysiology.

Introduction

Survival times of patients with glioblastoma (GBM; WHO-IV glioma), the most frequent and malignant type of adult brain tumour, remain dismal [1]. Proteomic analyses of glioma have identified numerous altered proteins but have mostly concentrated on whole cell lysates and been dominated by the high abundance proteins [2]. Prospective proteomic studies need to analyse relevant subcellular proteomes and assess protein–protein interactions between altered proteins to gain further insight into glioma pathophysiology and development of targeted therapies.

Mitochondrial dysfunction plays an important role in the pathogenesis of GBM [3–5]. Mitochondria are essential cellular organelles involved in numerous complex physiological processes including energy generation, regulation of cellular proliferation and apoptosis [5]. GBM, like many malignant cancers, favour abnormal energy production via aerobic glycolysis, and show an inherent resistance to apoptosis [6–8]. To provide an insight into mitochondrial dysfunction in GBM, we have quantified the proteomic

alterations in mitochondrial fractions from GBM using a label-free proteomics (LC–MS) approach. We highlight the extensive interactions between the altered proteins in relation to oxidative damage and energy metabolism, as well as proteins that are associated with the nuclear transcription factor hepatocyte nuclear factor 4 α (HNF4A), which plays a pivotal role in gut neoplasia and the targeting of oxidoreductase-related genes [9].

Materials and methods

Brain samples were obtained from patients undergoing resective brain tumour surgery after informed written consent (ethical approval: LREC/2004/4/16). GBM and control samples were resected from viable tumour tissue and peritumoural brain respectively (patient C1 as exception; see supplementary S1 for details). Peritumoural-control brain was determined using a BrainLAB MRI guided system (merged T1 contrast enhanced plus T2). For proteomics, fresh samples were snap-frozen immediately following resection and stored at -70°C prior to mitochondrial extraction. Irrespective of the pathology, the global proteomic signature of individual peritumoural-control samples could not be differentiated from the group proteomic signature (supplementary S1). For electron microscopy, samples were placed immediately after surgical excision into fixative (4 % paraformaldehyde, 5 % glutaraldehyde, 0.08 M sodium-cacodylate-buffer, pH 7.2).

Mitochondrial-enriched fractions were prepared from GBM ($n = 6$) and peritumoural-control brain ($n = 6$) using the Human Tissue Mitochondria-Isolation Kit (Mitosciences). Immunoblotting with COXI, COXIV and VDAC1 was performed on all samples prior to proteomic analysis to check the integrity of the mitochondrial-enriched fractions.

Mitochondrial Proteomics of GBM using LC–MS

Protein extracts (100 μg) from mitochondrial fractions were digested and cleaned on SCX column [10]. Capillary–HPLC–MSMS data were acquired using an on-line system consisting of a micro-pump coupled to a hybrid LTQ–Orbitrap XL instrument (using Xcalibur 2.0.7). HPLC–MS methods have been described previously [10–12].

LC–MS runs were analysed using the label-free intensity analysis software Progenesis (NonlinearDynamics, UK). MSMS data were searched using MASCOT Version 2.3 against a human plus-contaminant IPI database with 55413 sequences downloaded from www.ebi.ac.uk (v3.42). Variable methionine oxidation, STY phosphorylation, protein N-terminal acetylation and fixed cysteine carbamidomethylation were used in searches.

Progenesis normalises sample intensities and calculates protein intensities from MS peak data as the sum of MS-peak intensities of identified peptides. Protein intensities were used as a relative abundance measure between samples. Within group means were calculated to determine the fold-change and this data was used to calculate the p -values using one-way ANOVA. The data were converted using Pride converter v2.5.4 [13] and are available on the public data repository PRIDE (<http://www.ebi.ac.uk/pride/>; accession numbers 20946–20957). All proteins identified with ≥ 2 peptides are listed in supplementary S2. Differentially expressed proteins were only considered significant when detected by ≥ 2 peptides, ≥ 2 -fold-change and $p \leq 0.05$ for protein intensity change. Hierarchical clustering on the normalized protein intensity was performed using Rheatmap2.

Bioinformatic analysis of subcellular localisation and protein–protein interactions

All quantified proteins were uploaded to the Database for Annotation, Visualization and Integrated Discovery (DAVID) (<http://david.abcc.ncifcrf.gov> [14, 15]) to determine subcellular localization based on gene-ontology (GO). Cognizant of the fact that mitochondrial preparations are enriched in, but are not exclusively mitochondrial proteins, significantly altered proteins ($p \leq 0.05$, ≥ 2 -fold-change) included in the GO term mitochondrion (GO:0005739) were identified from the master list, filtered out, reported and used for network analysis.

Identifiers for altered proteins were uploaded to Ingenuity Pathway Analysis (IPA; <http://www.ingenuity.com>). Interactomes were algorithmically generated based on direct relationships (physical interactions and/or associations) between eligible proteins. Protein–protein interaction scores are putatively a measure of probability for the interactomes [16].

Mitochondrial morphology with electron microscopy (EM)

Following a minimum of 20 h in aldehyde fixative, GBM ($n = 6$) and peritumoural-control ($n = 7$) biopsies were dissected into 1–2 mm^3 pieces suitable for EM processing. Processing, embedding and staining were performed, as described [17]. Evaluation of tissue fixation was carried out by an assessor, blinded to the status of the tissue. Only samples judged to be well fixed under light microscopy were submitted for further analysis.

EM sections were evaluated on a JEOL-CX-100-II transmission electron microscope at 8000 \times magnification. Images were captured within 3 grid squares selected in a predetermined unbiased pattern.

A multiple squares grid mask was superimposed on the digitised electron micrographs. Mitochondria that lay beneath an intersection were evaluated on the basis of morphology, into one of three classes: normal (with cristae clearly visible over >50 % of the matrix), abnormal (swollen with most of the matrix lost), or uncertain (fewer than normal cristae or condensed) (see supplementary S3). The assessor was blinded to the nature of the tissue samples. A minimum of 119 mitochondria were assessed per tissue sample.

Results

Overview of proteomic data from mitochondrial fractions

A total of 902 proteins were identified. Hierarchical clustering of the 902 normalized protein intensities revealed two major clusters corresponding to GBM and peritumoural-control cohorts (Fig. 1a). Western-blotting using markers for outer (VDAC1) and inner (COX1, COXIV) mitochondrial membranes indicated that all three proteins were present in the mitochondrial-enriched fraction and absent in the post-mitochondrial supernatant fraction from GBM and peritumoural-control samples (supplementary S4). These data indicate that there has been minimal breakdown of mitochondrial membranes during the fractionation procedure, and that mitochondrial fractionation or integrity is not different in GBM compared to peritumoural-control brain.

Alterations in the mitochondrial proteome of GBM

The 902 proteins identified by mass spectrometry were categorised using DAVID and 256 proteins were classified as mitochondrially associated based on the GO designation *mitochondrion*. This fraction of mitochondrial (28 %) versus other proteins (72 %), is consistent with published studies using similar preparations [10, 18].

117 of these mitochondrial proteins were significantly ($p \leq 0.05$, ≥ 2 -fold change) altered between the GBM and peritumoural-control groups: 39 proteins increased and 78 proteins decreased in GBM. All proteins are listed with names and statistical parameters in supplementary S2, while the numbers of proteins in each category are summarised in supplementary S5. The top 40 altered proteins (ranked by p value) are listed in Table 1 and illustrative changes presented (Fig. 1b). Some proteins (for example, CAT, PRDX1, GPX4) display a small variation across the different samples, and others (for example NDUFA4, NDUFB10, NDUFV3; all Electron Transport Chain (ETC)

complex I proteins) display a broader variation, particularly in peritumoural-control samples.

Functional analysis of differentially expressed mitochondrial proteins

Functional categorization of the 117 mitochondrial proteins altered in GBM revealed two prominent functional groups associated with antioxidants and energy metabolism.

Antioxidants

A general increase in several proteins involved in antioxidant defence (including CAT, PRDX1, PRDX4 and SOD2) were observed in GBM, with the exception of GPX4, which was significantly decreased in GBM.

Energy metabolism (ETC, TCA cycle, lipid and amino acid metabolism)

Reductions in the levels of numerous proteins involved in energy metabolism were observed in GBM. Multiple components of the ETC were decreased in GBM (~40 proteins; including NDUFA4, NDUFB10, NDUFC2 and COX6B1). Of these ETC proteins, 23 proteins were components of ETC Complex-I. In contrast a number of proteins involved in lipid metabolism (for example, ACADM, DECR1 and SCP2) and amino acid synthesis and metabolism (AASS, LAP3, MTHFD1L and SHMT2) were increased in GBM. Also several proteins integral to energy production prior to the ETC were dysregulated in GBM: AK2, GATM, ME2 and SUCLG2 were increased; and CKMT1B, GLS, HK1, ME3 and SUCLA2 were decreased.

Other proteins of interest

Several proteins, for example BSG (increased in GBM), SNCB (decreased in GBM) and IDH3 (with IDH3A, IDH3G and IDH3B all decreased in GBM), did not fall into an obvious functional grouping but are pertinent to tumour pathophysiology (see “Discussion” section).

Interactomes of mitochondrial proteins altered in GBM

To further interrogate the proteomic data, putative interactions (“interactomes”) between mitochondrial proteins significantly altered in GBM were identified using IPA (supplementary S6) [26]. The seven high-scoring networks (score >20) are depicted in Fig. 2 and supplementary S7. Three of the highest scoring interactomes were related to components of the ETC, notably complex-I, IV and V and a further interactome described protein–protein interactions between the ETC and Synuclein (*inter alia*). The

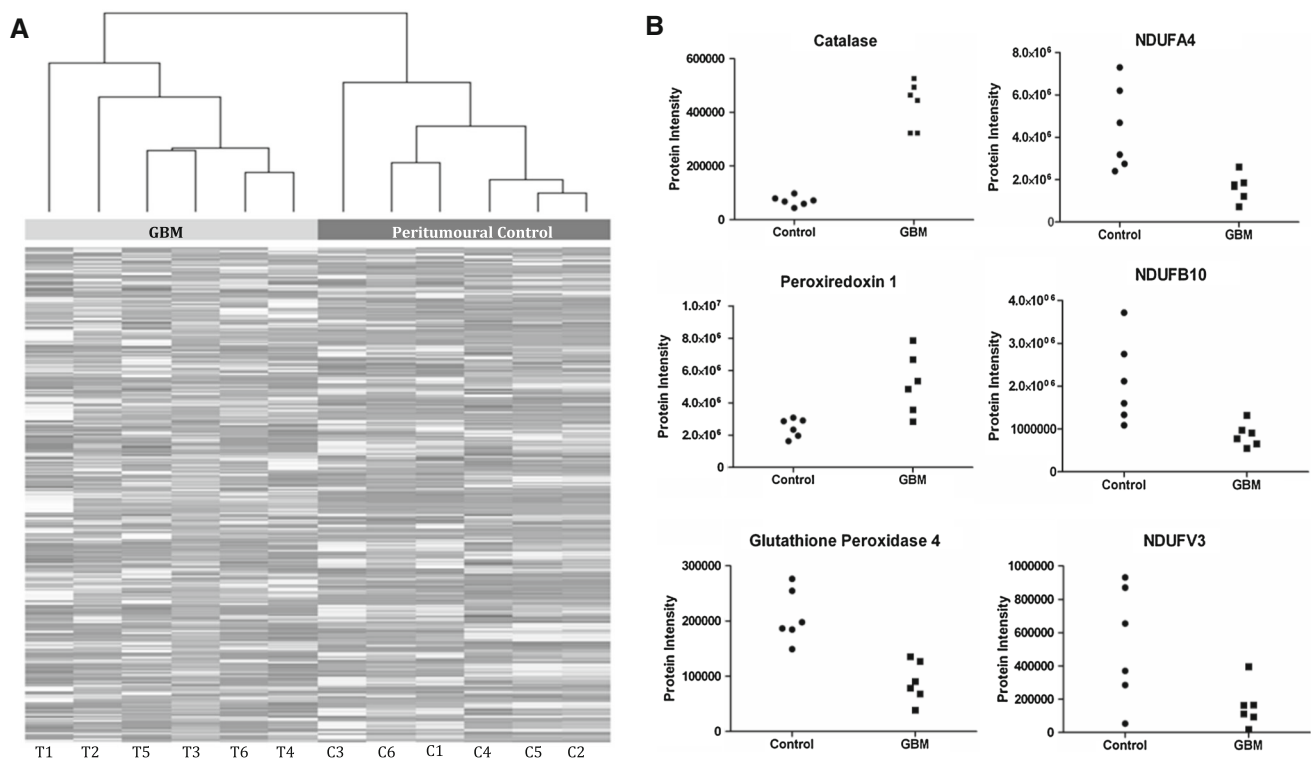

Fig. 1 Overview of proteomic data from mitochondrial fractions. Hierarchical clustering of the 902 proteins (normalised protein intensities) detected by LC–MS in mitochondrial fractions of GBM (T) and peritumoural control brain (C). Each column (in greyscale) represents the proteomic profile (intensities of the 902 proteins) in a single sample. Protein intensities were extracted from Progenesis software. The dendrogram (x-axis) provides a visual representation of sample–sample correlations, with correlated samples grouped in branches. Note there are two main branches to this dendrogram which

precisely correspond to the two experimental groupings GBM and peritumoural control. The data highlight that there are global differences in the mitochondrial enriched proteome in GBM compared to peritumoural control. Illustrative changes in 3 proteins associated with oxidative damage (catalase, peroxiredoxin 1 and glutathione peroxidase 4) and 3 proteins associated with the Electron Transport Chain (NDUFA4, NDUF10 and NDUFV3) in GBM relative to peritumoural controls. Each point represents an individual patient

interactome dominated by Complex-IV proteins also highlighted a cluster of isocitrate-dehydrogenase proteins (IDH3A, IDH3G and IDH3B), decreased in GBM. A high scoring network with the nuclear transcription factor HNF4A as an inserted hub protein links 10 proteins increased in GBM as well as 5 proteins reduced in GBM (Fig. 2b). The other two interactomes included one with proteins interacting with MYC and creatine-kinase, and another with interactions between proteins involved in ion-transport and related processes. The proteins involved in protecting the cells from oxidative damage (for example, CAT, SOD, PRDX1, GPX4) do not directly interact with each other despite similar functional roles but these appear in networks where their interactions with other proteins (altered in GBM) have been described.

Morphology of mitochondria in GBM

The ultrastructure of mitochondria in GBM was quantitatively assessed and compared to control brain using

Electron Microscopy (EM). In peritumoural-control brain, the ultrastructure of 69 % (range 44–81 %) of mitochondria analysed were normal (i.e. cristae visible with no swelling or condensed matrix) and 16 % (6–30 %) of mitochondria were abnormal (Fig. 3). In GBM, 11 % (4–30 %) of mitochondria were normal and 75 % (49–88 %) of mitochondria were abnormal (Fig. 3). 15 % of mitochondria in peritumoural-control brain and 14 % in GBM could not be unambiguously classified as either normal or abnormal.

Discussion

This study provides a comprehensive proteomic and morphological characterisation of mitochondria in GBM. Numerous alterations in the levels of mitochondrial proteins were detected in GBM compared to control brain. Multiple proteins associated with oxidative damage were up-regulated in GBM and multiple proteins involved in

Table 1 Mitochondrial proteins altered in GBM

The 40 most significantly different mitochondrial proteins in GBM relative to peritumoural controls ($p \leq 0.05$, ≥ 2 -fold change, ranked by p -value). For a list of all 117 significantly altered mitochondrial proteins ($p \leq 0.05$, ≥ 2 -fold change) see supplementary information S2. S2 also lists non-mitochondrial proteins significantly altered and all unaltered proteins identified with ≥ 2 peptides

The protein accession number (IPI), gene name, and protein name are listed for each altered protein, together with: ^a p -value evaluated by one-way ANOVA on intensity data (computed using Progenesis)

^b Ratio of the average protein intensity in GBM and control samples, measured by Progenesis

^c Number of peptides used for quantitation

^d Protein identification score (calculated by Mascot)

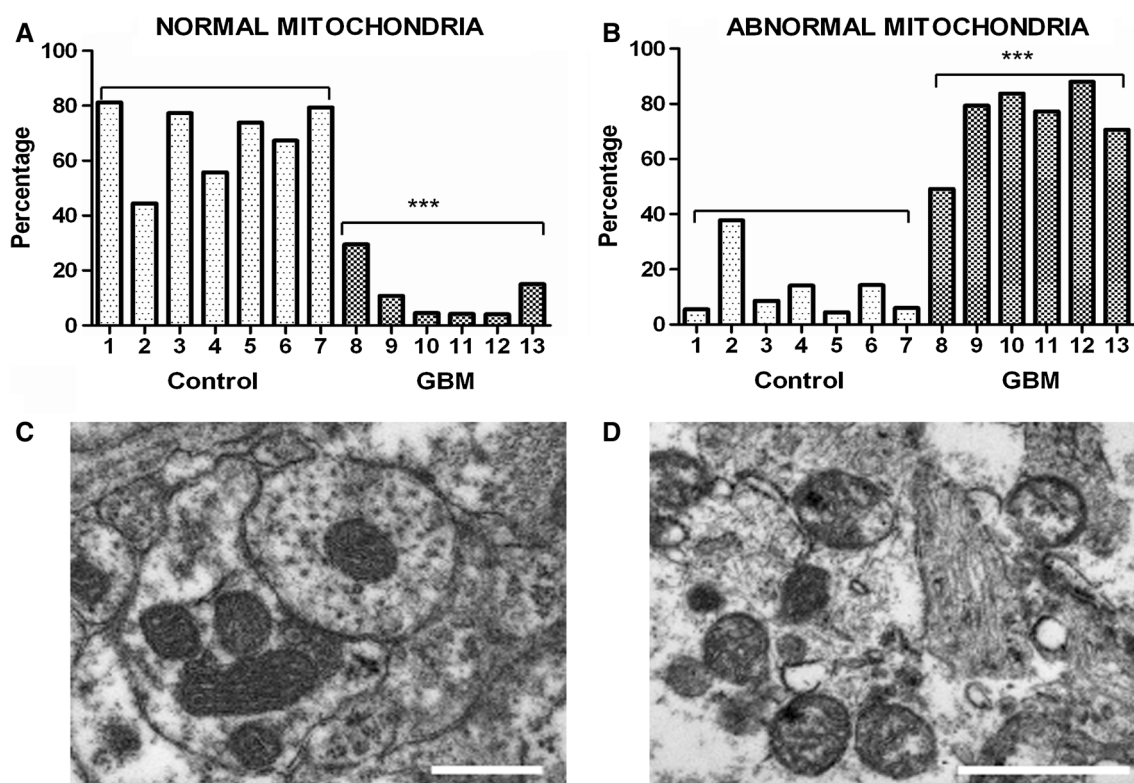

Fig. 3 Morphology of mitochondria in GBM. The morphology of ~150 mitochondria was assessed in each of 6 GBM and 7 peritumoural control samples using Electron Microscopy (EM). **a** Percentage of normal mitochondria (i.e. where cristae are visible throughout the mitochondria, or in at least 50 % of the mitochondrial interior area) in peritumoural control and GBM samples (each bar represents one sample; *** p -value = 0.0001); **b** Percentage of

abnormal mitochondria (i.e. with very few cristae, interior matrix condensed and dark or round swollen with interior missing) in peritumoural control and GBM samples (please see supplementary information S3 for more details; *** p -value = 0.0001). **c, d** Representative EM images of normal and abnormal mitochondria respectively. The scale bars represent 0.5 μm

energy metabolism were down-regulated. In addition a much greater prevalence of cristolysis was observed in GBM compared to control brain mitochondria by quantitative assessment of EM images. The abnormal mitochondrial ultrastructure could underlie the shift in energy generating pathways in GBM for cell survival and progression.

The role of reactive oxygen species (ROS) and antioxidants in cancer is highly complex. ROS can cause DNA damage that generates pro-oncogenic mutations, but a build up of ROS and damaged proteins in the mitochondria can also trigger apoptosis and autophagy [19]. ROS are a by-product of aerobic ATP generation. Increases in GBM in CAT, PRDX1, PRDX4 and SOD2 and a decrease in GPX4 may be a response to the increased ROS present due to the high energy demands of the GBM. Peroxiredoxin antioxidants are increased in various solid tumours [20–22] and PRDX1 is up-regulated in GBMs compared to low-grade gliomas. Peroxiredoxins 1 and 4 form a heterodimer and play a key role in regulating nuclear factor kB (NFkB) activity. NFkB is a transcription factor that modulates

oncogenesis, tumour progression and chemotherapy resistance in a range of cancers [23, 24]. CAT is an enzyme that converts H_2O_2 to H_2O and O_2 and plays a multifaceted role in pro- and anti-apoptotic pathways. Over-expression of CAT decreases ROS levels thereby reducing apoptosis, but also decreases sensitivity to tumour necrosis factor alpha (TNFα) (by reducing H_2O_2 [25]) which leads to increased resistance to apoptosis. SOD2 plays a dual role in tumorigenic progression, but generally overexpression of SOD2 enhances the metastatic phenotype that is reversed by efficient H_2O_2 scavenging [26]. The reduction of GPX4 is pro-oncogenic since GPX4 has been shown to halt tumour proliferation and progression [27]. Antioxidants in healthy cells protect against tumour genesis by preventing oxidative damage but in cells that are already aberrant inhibition of these antioxidants could generate catastrophic damage by inducing apoptosis [28].

Energy pathways (comprising TCA cycle, ETC, lipid and amino acid metabolism) were also found severely altered in this study, in agreement with aberrant energy metabolism in gliomas and other cancers [8, 29–32].

Multiple protein alterations integral to energy production prior to the ETC were detected (for example, AK2, CKMT1B, GATM, GLS, HK1, ME2, ME3, SUCLA2 and SUCLG2), with these changes emphasising a disruption rather than a coordinated response. An increase in ME2 was found which converts malic acid and NAD⁺ into pyruvate and NADH, increasing levels of NADH for the ETC [33]. SUCLG2 which catalyses GTP, succinate and CoA into GDP, phosphate and succinyl-CoA was markedly increased. In contrast, a decrease was seen in the ATP isoform SUCLA2 which reduces availability of succinyl-CoA [34]. The increase in GATM, which catalyses production of creatine precursor, suggests an increase in creatine which can act as a phosphate store in the brain to rapidly replenish ATP supplies [35]. Another altered protein, AK2, is found in the intermembrane space of mitochondria and catalyses the reversible reaction ATP and AMP into 2ADP. When AK2 is translocated from the nucleus to the cytoplasm it triggers apoptosis and AK2 knock-down decreases apoptosis. An increase in AK2 in the mitochondria may favour a decrease in translocation and therefore a decrease in apoptosis promoting tumour growth [36].

The ETC consists of five (I–V) transmembrane protein complexes that act in consort to transfer electrons and drive protons into the intermembrane space to create a proton motive gradient across the inner mitochondrial membrane and generate ATP [37]. Numerous ETC proteins not previously identified in whole cell lysate studies were detected in our study and the majority of these were down-regulated in GBM (including 23 Complex-I proteins) indicating that Complex-I function and oxidative phosphorylation (normal aerobic respiration) is reduced in GBM.

Proteins involved in lipid metabolism (for example, ACADM, ACOT7, DECR1, SCP2) and amino acid metabolism (for example, AASS, LAP3, MTHFD1, SHMT2) were up-regulated. ACADM and DECR1 are enzymes required for the mitochondrial β oxidation of lipids [38, 39] and SCP2 is a lipid transfer molecule that ensures a sufficient supply of lipids to the mitochondria [40]. AASS catalyses the metabolism of lysine to glutamate which can be converted to α -ketoglutarate, a component of the TCA cycle [41]. SHMT2 is a protein responsive to the pro-oncogenic gene cMyc and catalyses the conversion of serine to glycine with a single carbon by-product for cell proliferation [42].

Network analysis highlighted a cluster of altered mitochondrial proteins associated with the nuclear transcription factor HNF4A. Although frequently described as a tumour-suppressor gene, HNF4A plays a role in cancer initiation and intracellular protection against cancer-related ROS production [9]. HNF4A has also recently been shown to be expressed and regulated in meningioma brain tumours [43].

HNF4A interacts with proteins that are little characterised such as ACSS3, BDH1 and FDXR, and highlights the need for further functional investigations of these proteins in tumour pathogenesis.

A number of mitochondrial proteins with relevance to tumour pathophysiology were altered, including BSG, SNCB and three Isocitrate dehydrogenase 3 forms (IDH3A, IDH3B, and IDH3G). BSG is associated with tumour invasiveness, metastasis, drug resistance and glycolysis [44] and activates multiple pathways including NF κ B and JNK which stimulate matrix metallo-proteinases (MMP) [45]. MMPs promote invasion by breaking down the intracellular matrix. BSG levels in GBM tissue were more than twice that of control indicating a contributory role in tumour progression providing a potential therapeutic target. Calveolin1 is an effective inhibitor of BSG by reducing BSG glycosylation [46]. SNCB, known for its role in Alzheimer's disease, was decreased in GBM tissue 4-fold compared to peritumoural-control tissue and inhibits phospholipase D2 (PLD2) [47] which is oncogenic [48]. Restoration of SNCB levels may suppress tumour progression. Downregulated isoforms of IDH3 were also noted, and IDH1 and IDH2 mutations have recently been reported in gliomas [49]. IDH1 (cytoplasmic) and IDH2 (mitochondrial) catalyse the reaction *Isocitrate-dehydrogenase* + NADP⁺ \rightarrow 2- α -ketoglutarate(α KG) + CO₂ + NADPH. IDH1 mutations are present in low but not high-grade gliomas and preferentially occur in young patients with improved prognosis [50]. Both IDH1 and IDH2 mutations have a loss-of-function and gain-of-function consequence. No mutations of IDH3, which normally catalyse the same reaction as IDH1/IDH2 (but use NAD⁺ as substrate) have been noted in gliomas, so the consequence of its downregulation can only be extrapolated from reports on IDH1/IDH2. The reduction in IDH3 would produce the loss-of-function phenotype without the gain. Loss-of-function causes decreased α -KG and NADH, and the decreased α -KG results in an increased hypoxia inducible factor 1 alpha (HIF-1 α) which promotes glioma development [51].

We describe for the first time systematic differences in the mitochondrial proteome in GBM relative to peritumoural-control tissue. Although casual perusal of the data (for example Fig. 1b) offers tantalising suggestions of heterogeneity of particular protein levels in peritumoural control or GBM, the variance within the two groups are similar to that observed in our other studies (mouse, cell culture). The small sample size (groups of 6) relative to the number of proteins assessed (256) precludes meaningful subgroup analysis, of for example IDH1 mutations, methylation status and age related changes, despite its considerable clinical importance. The clear demonstration of biologically coherent changes in mitochondrial proteins in GBM

highlights the importance of further proteomic analysis of this brain pathology.
